

The Fading Memory Polynomial Velocity Strategy Applied To 1Min bar E-Mini Futures from 7/2007 –11/2008

Working Paper December 2008

Copyright © 2008 Dennis Meyers

This is a mathematical technique that fits a n^{th} order polynomial to the last T price bars but calculates the coefficients of the polynomial such that the error between the current n^{th} order polynomial and the current bar is weighted much higher than the error between the price T bars ago and the value of the n^{th} order polynomial T bars ago. As an example, if the latest price is at time t and the price made a turn at time bar $t-10$, then we do not want prices prior to $t-10$ effecting the current polynomial fit as much. As will be shown the most familiar case of this fading memory technique is the exponential moving average. The fading memory technique is in contrast to the Least Squares Polynomial fit, which weights all past errors between the polynomial and the price bar equally.

In previous working papers we showed how the application of a price curve generated by Nth Order Fixed Memory Polynomial Velocity could be used to develop a strategy to buy and sell futures intraday. The reasoning behind this type of system was to only trade when the price trend velocity was above a certain threshold. Many times prices meander around without any notable trend and this is considered noise. During these times we do not wish to trade because of the whipsaw losses that would occur from this type of price action. When a price trend finally starts, the velocity of that price trend moves above some minimum threshold value. Thus the velocity system would only issue a trade when certain velocity thresholds above “noise” levels are crossed.

The velocity system that we will use here to trade the E-Mini futures contract is called the Nth Order *Fading* Memory Adaptive Polynomial Velocity Strategy. The word “Adaptive” is used because the polynomial inputs change over time, adapting to the changing trading patterns of the E-Mini futures contract. The Nth Order Fading memory Adaptive Polynomial Velocity Strategy has a number of unknown inputs that we have to determine before we can use this strategy to trade. These unknown inputs to the Fading Memory Polynomial are the polynomial order, the optimum number of prices we need to determine the coefficients of the polynomial and finally the velocity thresholds. Here we will use Walk Forward Optimization and out-of-sample performance to determine the “best” polynomial inputs as well as how these inputs should change over time. We will use the nth Order Adaptive Polynomial Velocity System to trade the E-Mini futures contract on an intraday basis using one minute bar price data. To test this strategy we will use one minute bar prices of the E-Mini futures contract(ES) traded on the CME/Globex from June 25, 2008 to November 28, 2008.

The n^{th} Order Fading Memory Adaptive Polynomial Velocity Defined

The adaptive n^{th} order Fading Memory Polynomial Velocity is constructed and plotted at each bar by solving for the coefficients $b_1, b_2, b_3, \dots, b_n$ for the discrete orthogonal Meixner polynomials at each bar using the exponential decay factor $\alpha=(1-\beta)$ and the equation for b_j shown in the “Math” appendix of this paper. Then **Velocity(T+1)** is constructed from the equation shown in the “Math” appendix and plotted under the price chart.

The velocity of a 2^{nd} , 3^{rd} and 4^{th} order polynomial should change faster than the straight line (1^{st} order velocity). As observed from the 2^{nd} order velocity equation in the “Math” section, there is an acceleration component in the calculation of the velocity. This means that the 2^{nd} order velocity will reflect a change in the price trend much faster than the straight line velocity which does not have an acceleration component. The same is true for 3^{rd} and 4^{th} order velocities. Whether higher order polynomial velocities is an advantage or not we will let the computer decide when we let the computer search for the “best” polynomial degree as described below.

At each bar we calculate the n^{th} order (1^{st} through 4^{th}) fading memory polynomial velocity from the formulas in the “Math” appendix. As we will show below, optimization will determine the order for nth order polynomial velocity that will be used. When the velocity is greater than the threshold amount *vup* we will go long. When the velocity is less than the threshold amount *-vdn* we will go short.

Buy Rule:

IF Velocity is greater than the threshold amount *vup* then buy at the market.

Sell Rule:

IF **Velocity** is less than the threshold amount **-v_{dn}** then sell at the market.

The strategy follows the velocity curve. When the velocity is greater than the threshold amount **v_{up}** a buy signal is issued. The threshold **v_{up}** serves as a noise filter. That is, price noise creates a lot of small back and forth velocity movement. Unless the velocity can break some threshold to the upside, no trade is issued and the move is considered price noise. The same logic holds for the sell threshold **v_{dn}**.

Intraday Bars Exit Rule:

Close the position 5 minutes before the ES close (no trades will be carried overnight).

Intraday Bars First Trade of Day Entry Rule:

Ignore all trade signals before 10:00 EST (30 minutes after the open). For the Buy and Sell rules above we have included a first trade of the day entry rule. We've included this rule because often there are gaps in the open creating immediate system buys and sells. Many times these gaps are closed creating a losing whipsaw trade. In order to avoid the opening gap whipsaw trade problem we've delayed the first trade of the day for 30 minutes until after 10:00 EST

Discussion of E-Mini Prices

The E-Mini (ES) is traded on Globex and on the trading floor at the CME. On Globex the ES is traded on a 23hour basis. The CME hours for floor trading (RTH) are 8:30 to 15:15 CST. We have restricted our study to only trading the ES during the 8:30 to 15:15 hours.

Testing The Polynomial Velocity System Using Walk Forward Optimization

There will be four strategy parameters to determine:

1. **degree**, degree=1 for straight line velocity, degree=2 for 2nd order velocity, etc.
2. **alpha** = $(1-\beta)$ The exponential decay weight for the Nth Order Fading Memory Polynomial calculation.
3. **v_{up}**, the threshold amount that velocity has to be greater than to issue a buy signal
4. **v_{dn}**, the threshold amount that velocity has to be less than to issue a sell signal

To test this system we will use one minute bar prices of the E-Mini (ES) futures contract traded on the CME/Globex and known by the symbol ES for the 75 weeks from June 25, 2007 to November 28, 2008.

We will test this strategy with the above ES 1 min bars on a walk forward basis, as will be described below. To create our walk forward files we will use the **add-in** software product called the Power Walk Forward Optimizer (PWFO). In TradeStation (TS), we will run the PWFO strategy **add-in** along with the nth Order Fading Memory Polynomial Velocity Strategy on the ES 1min data from June 25, 2007 to November 28, 2008. The PWFO will breakup and create 70 calendar month test sections along with their corresponding one calendar week out-of-sample sections from the 75 weeks of ES (see Walk forward Testing below).

What Is A Test Section and Out-Of-Sample Section?

Whenever we do a TS optimization on a number of different strategy inputs, TS generates a report of performance metrics (total net profits, number of losing trades, etc) vs these different inputs. If the report is sorted on say the total net profits (**tnp**) performance metric column then the highest **tnp** would correspond to a certain set of inputs. This is called a **test section**. If we choose a set of strategy inputs from this report based upon some performance metric we have no idea whether these strategy inputs will produce the same results on future price data or data they have not been tested on. Price data that is not in the test section is defined as **out-of-sample data**. Since the performance metrics generated in the test section are mostly due to "curve fitting" (see Walk Forward Out-of-Sample Testing section below) it is important to see how the strategy inputs chosen from the test section perform on out-of-sample data.

What Does The Power Walk Forward Optimizer (PWFO) Do?

The PWFO is a TS *add-in* that breaks up the TS optimization run into a number of user selectable test and out-of-sample sections. The PWFO prints out the test sample performance **and the out-of-sample performance results**, on one line, for each case or input variable combination that is run by the TradeStation(TS) optimization module to a user selected spreadsheet comma delimited file. The PWFO can generate up to 500 different test and out-of-sample date optimization files in one TS run, saving the user from having to generate optimization runs one at a time. The PWFO output allows you to quickly determine whether your procedure for selecting input parameters for your strategy just curve fits the price and noise, or produces statistically valid out-of-sample results. In addition to the out-of-sample performance results presented for each case, 30+ superior and robust performance metrics (many are new and never presented before) are added to each case line in the test section and printed out to the comma delimited file. These 30+ performance metrics allow for a superior and robust selection of input variables from the test section that have a higher probability of performing well on out-of-sample data (Please see Appendix 2 for a listing of these performance metrics).

For our computer run we will have the PWFO breakup the 74 weeks of ES one minute bar price data into 70 test/out-of sample files. The test sections will be 1 month and the out-of-sample section will be the one week following the test section. As an example the first test section would be from 6/28/2007 to 7/27/2007 and the out-of-sample section would be from 7/30/2007 to 8/3/2007.(our test and out-of-sample sections always end on a Friday). We would then move everything ahead a week and the 2nd test section would be from 7/5/2007 to 8/3/2007 and the out-of-sample section would be from 8/6/2007 to 8/10/2007. Etc.

The PWFO 70 test/out-of-sample section dates are shown in **Table 1** on page 7 below. We will then use another software product called the Walk Forward Performance Metric Explorer (WFPME) on each of the 70 test and out-of-sample(oos) sections generated by the PWFO to find the best test section performance *filter* that determines the system input parameters (*degree, N, vup, vdn*) that will be used on the out-of-sample data. Detailed information about the PWFO and the WFPME can be found at www.meyersanalytics.com

For the test data we will run the TradeStation optimization engine on the 75 weeks of ES 1 min bars with the following ranges for the nth order fading memory polynomial velocity strategy input variables.

1. degree from 1 to 4
2. N from 20 to 70 in steps of 10.
3. vup from 0.25 to 3 steps of 0.25
4. vdn from 0.25 to 3 in steps of 0.25
- 5.

Note: I use N because it gives a better understanding of how many bars of past data are approximately being used. **N** and **α** (**$\alpha=1-\beta$**) are approximately related by the formula **$\alpha=2/(1+N)$** . N is converted to **α** by this formula in the Nth Order Fading Memory Polynomial calculation

This will produce 3456 different cases or combinations of the input parameters for each of the 50 PWFO output files.

Walk Forward Out-of-Sample Testing

Walk forward analysis attempts to minimize the curve fitting of price noise by using the law of averages from the Central Limit Theorem on the out-of-sample performance. In walk forward analysis the data is broken up into many test and out-of-sample sections. Usually for any system, one has some performance metric selection procedure which we will call a *filter* used to select the input parameters from the optimization run. For instance, a *filter* might be all cases that have a profit factor (PF) greater than 1 and less than 3. For the number of cases left, we might select the cases that had the best percent profit. This procedure would leave you with one case in the test section output and it's associated strategy input parameters. Now suppose we ran our optimization on each of our many test sections and applied our filter to each test section output. We would then use the strategy input parameters found by the *filter* in each test section on the out-of-sample section immediately following that test section. The input parameters found in each test section and applied to each out-of-sample section would produce independent net profits and losses for each of the out-of-sample sections. Using this method we now have "x" number of independent out-of-sample section profit and losses from our filter. If we take the average of these out-of-sample section net profits and losses, then we will have an estimate of how our system will perform on average.

Due to the Central Limit Theorem, as our sample size increases, the spurious noise results in the out-of-sample section performance tend to average out to zero in the limit leaving us with what to expect from our system and filter. Mathematical note: This assumption assumes that the out-of-sample returns are from probability distributions that have a finite variance.

Why use the walk forward technique? Why not just perform an optimization on the whole price series and choose the input parameters that give the best total net profits or profit factor? Surely the price noise cancels itself out with such a large number of test prices and trades. Unfortunately, nothing could be farther from the truth! Optimization is a misnomer and should really be called combinatorial search. As stated above, whenever we run a combinatorial search over many different combinations of input parameters on noisy data on a fixed number of prices, ***no matter how many***, the best performance parameters found are guaranteed to be due to “***curve fitting***” the noise and signal. What do we mean by “***curve fitting***”? The price series that we trade consists of random spurious price movements, which we call noise, and repeatable price patterns (*if they exist*). When we run, for example, 5000 different input parameter combinations, the best performance parameters will be from those system input variables that are able to produce profits from the price pattern ***and*** the random spurious movements. While the price patterns will repeat, the same spurious price movements will not. If the spurious movements that were captured by a certain set of input parameters were a large part of the total net profits, then choosing these input parameters will produce losses when traded on future data. These losses occur because the spurious movements will not be repeated in the same way. This is why system optimization or combinatorial searches with no out-of-sample testing cause losses when traded in real time from something that looked great in the test section. Unfortunately it is human nature to extrapolate past performance to project future trading results and thus results from curve fitting give the illusion, a modern “siren call” so to speak, of future trading profits.

In order to gain confidence that our input parameter selection method using the optimization output of the test data will produce profits, we must test the input parameters we found in the test section on out-of-sample data. In addition, we must perform the test/out-of-sample analysis many times. Why not just do the out-of-sample analysis once? Well just as in Poker or any card game, where there is considerable variation in luck from hand to hand, walk forward out-of-sample analysis give considerable variation in month to month out-of-sample profit “luck”. That is, by pure chance we may have chosen some input parameter set that did well in the test section data ***and*** the out-of-sample section data. In order to minimize this type of “luck”, statistically we must repeat the walk forward out-of-sample (oos) analysis over many test/oos sections and take an average of our monthly results over all out-of-sample sections. This average gives us an expected monthly return and a standard deviation of monthly returns which allows us to statistically estimate the expected equity and it’s range for N months in the future.

Finding The Strategy Input Parameters in The Walk Forward Test Sections

The PWFO generates a number of performance metrics in the test section. (Please see appendix II for a listing of these performance metrics). The question we are attempting to answer statistically, is which performance metric or combination of performance metrics (which we will call a ***filter***) in the test section will produce strategy inputs that produce statistically valid profits in the out-of-sample section. In other words we wish to find a metric ***filter*** that we can apply to the test section that can give us strategy inputs that will produce, on average, good trading results in the future. The PWFO produces a total of 32 different performance metrics in the test section. If we have 3456 different input variations or cases then the test section consists of 32 columns of performance metrics for each of the 3456 input cases or rows.

An example of a simple filter would be to choose the row in the test section that had the highest net profit or perhaps a row that had one the best performance metric from one of the other 32 PWFO metrics. Unfortunately it was found that this type of simple filter very rarely produces good out-of-sample results. More complicated metric filters can produce good out-of-sample results minimizing spurious price movement biases in the selection of strategy inputs.

Here is an *example* of a better more complicated ***filter***. First, because in real time it is difficult to sustain more than five losses in a row and still keep trading, we will eliminate all those ***test section*** case rows that have more than 5 losses in a row (***LR***). We will further require that the number of trades (***NT***) in the test section be greater than 10. We require this so we can eliminate inputs that produce very few trades. One month is approximately 22 trading days so we are requiring at least a trade every other day on average. After using a ***NT*** and ***LR*** filter as just described

there can still be 100's of rows left in the PWFO file. The PWFO generates the metric **LLT** which is the Largest losing trade in Test Section for a particular set of inputs in the test section. Let us choose the five rows that contain the **Bottom 5 LLT** values from the rows that are left from the **NT-LR** screen. In other words we sort **LLT** from high to low, eliminate the rows that have **NT<10** and **LR>5** and then choose the Bottom 5 Rows of whatever is left. This particular filter will now leave 5 cases or rows in the PWFO file that satisfy these filter conditions. We call this filter **b5LLT|5:10** where b5LLT means the Bottom 5 LLT Rows left *after* the NT-LR filter. Suppose for this filter, within the 5 PWFO rows that are left, we want the row that has the maximum PWFO **b0** metric in the test section where **b0** is the slope of the equity regression line in the test section for a given set of inputs(see appendix 2 for definition). This would produce a filter named **b5LLT|5:40-b0**. This filter leaves only one row in the PWFO test section with its associated strategy inputs and out-of-sample net profit in the out-of-sample section. This particular **b5LLT|5:40-b0** filter is then calculated for each of the PWFO files and the average out-of-sample performance is calculated. In addition many other important out-of-sample performance statistics for this filter are calculated and summarized. **Appendix 3** shows such a computer run along with a small sample of other filter combinations that are constructed in a similar manner. Row 3 of the sample output in Appendix 3 shows the results of the filter discussed above.

Bootstrap Probability of Filter Results. Using modern "Bootstrap" techniques, we can calculate the probability of obtaining each filter's total out-of-sample *net* profits by chance. By *net* we mean subtracting the cost and slippage of all round trip trades from the total out-of-sample profits. Here is how the bootstrap technique is applied. Suppose for this example, we calculate the total out-of-sample net profits(tOnpNet) of 961 different **TopN-Metric- LR-NT** filters. A mirror filter is created for each of the 961 filters. However, instead of picking an out-of-sample net profit(OSNP) from a filter row, the mirror filter picks a *random* row's OSNP in each of the 70 PWFO files. Each of the 961 mirror filters will choose a random row's OSNP of their own in each of the 70 PWFO files.. At the end, each of the 961 mirror filter will have 70 *random* OSNP's picked from the rows of the 70 PWFO files. The sum of the 70 random OSNP picks for each mirror filter will generate a random total out-of-sample net profit(tOnpNet). The average and standard deviation of the 961 mirror filter's different random tOnpNets will allow us to calculate the chance probability of each **TopN-Metric- LR-NT** filter's tOnpNet. Thus given the mirror filter's bootstrap random tOnpNet average and standard deviation, we can calculate the probability of obtaining the TopN-Metric-PF-LR-NT filter's tOnpNet by pure chance alone. In addition since for this run there are 961 different filters, we can calculate the expected number of cases that we could obtain by pure chance that would match or exceed the tOnpNet of the filter we have chosen or 961 X tOnpNet Probability. For our filter in row 3 in Appendix 3 the expected number of cases that we could obtain by pure chance that would match or exceed the \$38933 is $961 \times 9.33 \times 10^{-4} = 0.897$. This is less than one case so it is improbable that our result was due to pure chance.

The run shown in appendix 3 reveals that the following filter will produce the most consistent and reliable out-of-sample results.

Filter: #Trds>=10 and LR<=5 and Bottom 5 LLT

Where:

- **LR** = Maximum consecutive losses in a row in test optimization section. Since in real time it is tough to sustain more that five losses in a row and still keep trading, we will eliminate all those cases that have more than five losses in a row
- **NT** = The number of trades for a particular set of inputs in the test section.
- **LLT** = The Largest losing trade in Test Section for a particular set of inputs in the test section.

The first part of the filter chooses those rows or cases out of the 961 rows in each PWFO file test(in-sample) section that satisfy the criteria **LR<=5 and NT>=10** . After using a NT and LR filter, there can still be 100's of rows left in the PWFO file. The PWFO generates the metric **LLT** which is the **Largest Losing Trade** of all trades for a particular set of inputs in the test section. Let us choose the five rows that contain the **Bottom 5 LLT** values from the rows that are left from the **NT-LR** screen.. This particular filter will now leave 5 cases or rows in the PWFO file that satisfy these filter conditions. We call this filter **b5LLT|5:10** where b5LLT means the Bottom 5 LLT Rows left *after* the NT-LR filter. Within the 5 PWFO rows that are left, we want the row that has the maximum PWFO **b0**

metric in the test section where **b0** is the equity curve acceleration(see appendix 2 for definition). This **Filter** or selection procedure will leave only one choice for the system input values of **degree, N, vup, vdn**. We then use these input values found in the test section by the **Filter** on the **next week** of one minute bar ES **out-of-sample** price bars **following** the test section.

Results

Table 1 on page 8 below presents a table of the 70 test and out-of-sample windows , the selected optimum parameters and the weekly out-of-sample results using the filter described above.

Figure 1 presents the out-of-sample 1 minute bar chart of ES for 11/24/2008-11/26/2008 with the Velocity Indicator and all the buy and sell signals for that date.

Discussion of System Performance

In Appendix 3 Row 3 of the spreadsheet filter output are some statistics that are of interest for our filter. **BE** is the break even weeks. Assuming the trade average and standard deviation for this filter are from a normal distribution, this is how many weeks we need to trade this strategy so that we have a 99% probability that the equity after those number of weeks will be greater than zero. BE is 18 weeks for this filter. This means we would have to trade this strategy for at least 18 weeks to have a 99% probability that our equity would be positive. Another interesting statistic is **Blw**. Blw is the maximum number of weeks the OSNP equity curve failed to make a new high. Blw is 8 weeks for this filter. This means that 8 weeks was the longest time that the equity for this strategy failed to make a new equity high.

To see the effect of walk forward analysis, take a look at **Table 1**. Notice how the input parameters **pw, N, vup and vdn** take sudden jumps from high to low and back . This is the walk forward process quickly adapting to changing volatility conditions in the test sample. In addition, notice how often **degree** changes from a straight line velocity with **degree=1** to a 2nd, 3rd and 4th order velocity with **degree= 2, 3 and 4**. The 3rd and 4th order velocities, due to the higher order components, change much faster than the straight line velocity. When the data gets very noisy with a lot of spurious price movements, it's better to have the velocity change slower filtering out the noisy data. During other times when the noise level is not as much it is better to have the velocity break its **vup** and **vdn** barriers faster to get onboard a trend faster. This is what the filter is doing. When there is a lot of noise in the test section it switches to the 1st or 2nd order curve velocity. When the noise level is lower in the test section, it switches to the faster changing 3rd or 4th order curve velocity.

Using this filter, the strategy was able to generate \$38,933 net equity after commissions and slippage trading one ES contract for 70 weeks. Note \$25 roundtrip commission and slippage was subtracted from each trade and no positions were carried over night. The largest losing week was -\$2325 and the largest drawdown was -\$2325. The longest time between new equity highs was 8 weeks.

From Table 1 there were 45 weeks that had a positive net profit and the average of those 45 weeks was \$1110. There were 17 weeks that had a negative net profit and the average of this 17 week net losses was -\$648.

In observing Table 1 we can see that this strategy and filter made trades from a low of 1 trade/week to a high of 38 trades/week with an average of 7.2 trades/week. The strategy seemed to wait for really strong trends and then initiate a buy or sell. There were many weeks that have no trades. In observing the chart from 11/24/08 – 11/26/08 we can see the strategy trading mostly only when there is a big trend action.

Given 24 hour trading of the E-Mini, restricting the strategy to trade only from 9am to 3:10pm caused the strategy to miss many profitable trends opportunities when Asia and then Europe opened trading in the early morning. Further research will include the A.M. time zones.

LR= Maximum consecutive loses in a row in test optimization section

NT = Minimum number of trades in the test section.

LBR = the **Total Losing Bars** of all trades for a particular set of inputs in the test section.

osnp = Monthly Out-of-sample gross profit in \$

NOnp\$25 = Monthly Out-Of-Sample Net Profit in \$ = **osnp-ont*25**.

NetEq = running sum of the monthly out-of-sample net profits in \$

ollt = The largest losing trade in the out-of-sample section in \$.

odd = The close drawdown in the out-of-sample section in \$.

ont = The number of trades in the out-of-sample month.

avosnp = The average out-of-sample profit per trade for that month \$

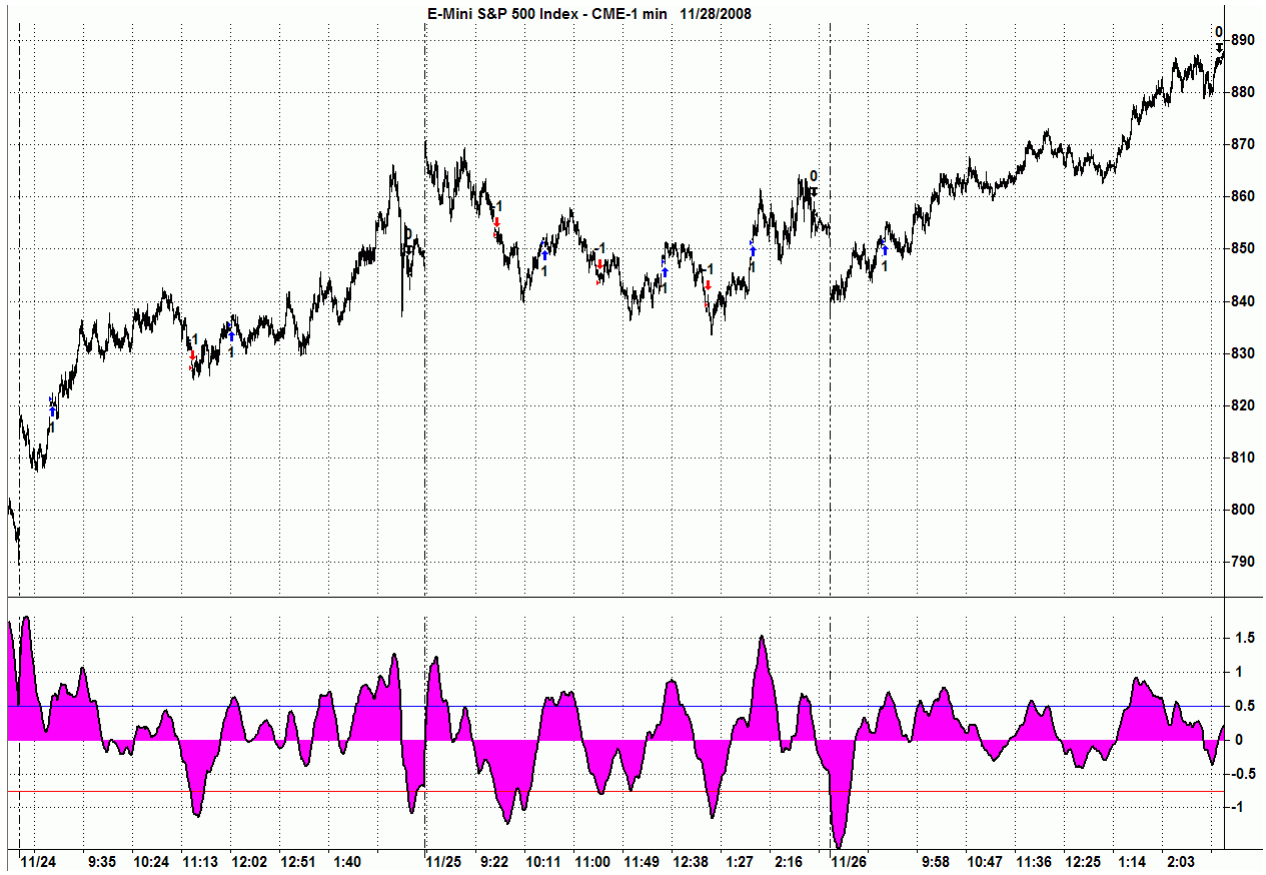

pw = polynomial degree. degree=2 for parabolic curve velocity, degree=3 for 3rd order velocity, etc.

N = is the number of bars lookback period to calculate the polynomial **velocity**.

vup =, the threshold amount that velocity has to be greater than to issue a buy signal

vdn =, the threshold amount that velocity has to be less than to issue a sell signal

Figure 2 Walk Forward Out-Of-Sample Performance Summary for ES Fading Memory Polynomial Velocity System 1 minute bar chart of ES from 11/24/08-11/26/2008

Appendix I: n^{th} Order Fading Memory Polynomial Next Bar's Forecast Math

What is The N^{th} Order Fading Memory Polynomial ?

This is a mathematical technique that fits a n^{th} order polynomial to the last T price bars but calculates the coefficients of the polynomial such that the error between the current n^{th} order polynomial and the current bar is weighted much higher than the error between the price T bars ago and the value of the n^{th} order polynomial T bars ago. As an example, if the latest price is at time t and the price made a turn at time bar $t-10$, then we do not want prices prior to $t-10$ effecting the current polynomial fit as much. As will be shown the most familiar case of this fading memory technique is the exponential moving average. The fading memory technique is in contrast to the Least Squares Polynomial fit, which weights all past errors between the polynomial and the price bar equally.

Consider a time series $x(t)$ where t is an integer value (a price bar number) like the number of days or minutes, etc from some starting time. Suppose we want to find at some given time some n^{th} -degree polynomial that fits the data well at current and recent prices but ignores the fit as we move into the distant past. One way to construct this type of fit would be to weight the past data with a number that got smaller and smaller the further back in time we went. If we let the polynomial function be represented by the symbol $p(t-\tau)$ where $p(t-0)$ is the current value of the polynomial, $p(t-1)$ is the previous value of the polynomial, etc., then an error function can be formed that consists of the weighted sum of the squared difference between the price series $x(t-\tau)$ and the polynomial $p(t-\tau)$ given by

$$\text{error} = \sum \beta^{\tau} (x(t-\tau) - p(t-\tau))^2 \quad \tau=0 \text{ to } \infty \quad (1)$$

where $0 < \beta < 1$ and β^{τ} is much much less than 1 for large τ .

It turns out that if we let the n^{th} degree polynomial $p(t-\tau)$ be constructed as a linear combination of orthogonal polynomials called Meixner polynomials then minimizing the error with respect to the coefficients of the orthogonal polynomials yields the best estimate of $x(t-\tau)$ as $x_{\text{est}}(t-\tau)$ and given by the equation

$$x_{\text{est}}(t-\tau) = (1-\beta) \sum_{k=0}^n \beta^k b_{k,t} \Phi_k(t) |_{\tau} \quad (2)$$

Where

$$\Phi_n(t) = \sum_{k=0}^n \binom{n}{k} \binom{t}{k} z^k$$

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}$$

$$b_{j,t} = \sum_{k=0}^{\infty} \beta^k \Phi_j(k) x(t-k)$$

$$z = 1 - 1/\beta$$

where n is the polynomial degree, $\Phi_k(\tau)$ are the Meixner polynomials of degree k ($k=0$ to n), and $b_k(t)$ are the coefficients that minimize the error of equation (1). Generally the summation for $b_j(t)$ can be terminated when $\beta^k \ll 1$.

Appendix I: n^{th} Order Fading Memory Polynomial Next Bar's Forecast Math

For the exact mathematical solutions that produce equation (2) and the mathematical descriptions of the Meixner polynomials refer to Reference 1.

To yield the 1 day ahead prediction the above equation becomes;

$$x_{\text{est}}(t+1) = (1-\beta) \sum_{k=0}^n \beta^k b_{k,t} \Phi_k(-1) \quad k=0 \text{ to } n \quad (3)$$

After some algebraic manipulation with the Meixner polynomials the $b_{k,t}$ coefficients satisfy the following recursive relationship. (see Reference 1)

$$b_{k,t} = \beta b_{k,t-1} + b_{k-1,t} - b_{k-1,t-1}$$

One case is of immediate interest where the polynomial is a constant, that is $n=0$.

For this case the solution to equation (3) can be found after some algebraic manipulation to be:

$$X0_{\text{est}} = \beta * X0_{\text{est}}[1] + (1-\beta) * x(t) \quad (4)$$

Where $X0_{\text{est}}[1]$ is the previous estimated value, $x(t)$ is the current bar's price and where the 0 in $X0_{\text{est}}$ indicates that we are estimating a polynomial of degree 0 or simply a constant. If a change of variables is made letting $\alpha = (1-\beta)$ then equation (4) becomes:

$$X0_{\text{est}} = (1-\alpha) * X0_{\text{est}}[1] + \alpha * x(t) \quad (5)$$

This is the familiar formula for the exponential moving average.

Higher orders of n don't yield such compact solutions as the case where $n=0$. equations

$$P_f(T+1) = (1-\beta) [b_{0,t} \phi_{0|t=-1} + \beta b_{1,t} \phi_{1|t=-1} + \beta^2 b_{2,t} \phi_{2|t=-1} + \dots + \beta^n b_{n,t} \phi_{n|t=-1}]$$

$$\text{Velocity} = (dP_f/dt)_{(T=-1)} = (1-\beta) [\beta b_{1,t} * (d\phi_1/dt)_{|t=-1} + \beta^2 b_{2,t} * (d\phi_2/dt)_{|t=-1} + \dots + \beta^n b_{n,t} * (d\phi_n/dt)_{|t=-1}]$$

$$\text{Accel} = (d^2P_f/d^2t)_{(T=-1)} = (1-\beta) [\beta^2 b_{2,t} * (d^2\phi_2/d^2t)_{|t=-1} + \beta^3 b_{3,t} * (d^2\phi_3/d^2t)_{|t=-1} + \dots + \beta^n b_{n,t} * (d^2\phi_n/d^2t)_{|t=-1}]$$

The n^{th} Order Fading Memory Forecast Next Bar's Price System Defined

The least squares forecast is constructed by solving for the coefficients $b_0, b_1, b_2, \dots, b_n$ recursively at each bar using the last T bars of closing prices and the Discrete Orthogonal Meixner Polynomial equations above. Then $P_f(T+1)$ is constructed from the equation above and plotted under the price chart. In general what we will be doing is following the plotted curve of P_f which is calculated at each bar from the previous T bars. When the curve increases by a percentage amount *pctup* from the previous prior low of the curve we will go long. When the curve falls by the percentage amount *pctdn* from the previous prior high of the curve we will go short

Buy Rule:

- IF P_f has moved up by more than the percentage amount of *pctup* from the lowest low recorded in P_f while short then buy at the market.

Sell Rule:

Appendix I: n^{th} Order Fading Memory Polynomial Next Bar's Forecast Math

- IF P_f has moved down by more than the percentage amount $pctdn$ from the highest high recorded in P_f while long then sell at the market.

The n^{th} Order Fading Memory Forecast Next Bar's Velocity System Defined

The least squares forecast is constructed by solving for the coefficients $b_0, b_1, b_2, \dots, b_n$ recursively at each bar using the last T bars of closing prices and the Discrete Orthogonal Meixner Polynomial equations above. Then **Velocity** = $dP_f(T+1)/dt$ is constructed from the velocity equation above and plotted under the price chart. In general what we will be doing is following the plotted curve of **Velocity** which is calculated at each bar from the previous T bars. When the velocity is greater than a threshold amount vup we will go long. When the velocity is less than a threshold amount $-vdn$ we will go short.

Buy Rule:

IF **Velocity** is greater than the threshold amount vup then buy at the market.

Sell Rule:

IF **Velocity** is less than the threshold amount $-vdn$ then sell at the market.

The n^{th} Order Fading Memory Forecast Next Bar's Acceleration System Defined

The least squares forecast is constructed by solving for the coefficients $b_0, b_1, b_2, \dots, b_n$ recursively at each bar using the last T bars of closing prices and the Discrete Orthogonal Meixner Polynomial equations above. Then **Acceleration** = $d^2P_f(T+1)/d^2t$ is constructed from the acceleration equation above and plotted under the price chart. In general what we will be doing is following the plotted curve of **Acceleration** which is calculated at each bar from the previous T bars. When the acceleration is greater than a threshold amount aup we will go long. When the velocity is less than a threshold amount $-adn$ we will go short.

Buy Rule:

IF **acceleration** is greater than the threshold amount aup then buy at the market.

Sell Rule:

IF **acceleration** is less than the threshold amount $-adn$ then sell at the market.

Explanation of The logic Behind The New Performance Metrics.

A number of performance statistics are new. This section will explain the logic behind the selection of these new statistics.

- **std - Trade Standard Deviation.**
This is the standard deviation of the trade profits/losses in dollars.
- **t - Student t-statistic.** Used to determine the probability that the Average Trade Profit $(\text{tnp}/nT) < 0$. Statistically, high values of t indicate that there is a very small probability that the sample average trade profit on the spreadsheet is \leq zero and a random number. In real life, I find that if I screen out the top 5% of t values in Excel, I screen out a lot of curve fit input parameters. Same goes for mkr.
- **mlb - Median Of The Trade Losing Bars.**
Each losing trade takes a certain number of bars. If we order the number of bars each losing trade takes then the median of all the losing trade bars is a robust statistic. We take the median of the losing trades bars to minimize the effect of large and small losing trade bars that may be outliers that distort this statistic.
- **mwb -Median Of The Trade Winning Bars**
Each winning trade takes a certain number of bars. If we order the number of bars each winning trade takes then the median of all the winning trade bars is a robust statistic. We take the median of the winning trades bars to minimize the effect of large and small winning trade bars that may be outliers that that distort this statistic.
- **mru-p – Median of All Trades(Maximum Trade Runup Minus Final Trade Profit)**
This statistic measures the difference between the maximum profit (trade runup) of each trade and the final profit of the trade. mru is the median of this difference for all trades for the given input variables. The closer the final trade profit is to the maximum trade profit, the better the performance of the input variable. Thus we would want the median to be as small as possible. We use the median for this statistic, because we do not want the statistic distorted by a few outlier trades
- **mp-rd – Median of All Trades(Final Trade Profit Minus Maximum rundown of Trade).**
This statistic measures the difference between the final profit of each trade and the maximum trade loss (rundown) of the trade. The farther the final trade profit is from the maximum trade drawdown, the better the performance of the input variable. Thus, we would want the median to be as large as possible. We use the median for this statistic, because we do not want the statistic distorted by a few outlier trades
- **mpft - Median Of The Winning Trades.**
This is the median of the winning trade profits. We take the median of the winning trades to minimize the effect of large winning trades that may be outliers that are not repeatable.
- **mlos -Median Of The Losing Trades**
This is the median of the losing trade losses. We take the median of the losing trades to minimize the effect of large losing trades that may be outliers that are not repeatable.
- **p/l – mpft/|mlos|.**
This is the ratio of mpft to absolute value of mlos. A high ratio indicates robustness indicating that the statistic of the median of the winning trades to losing trades is not caused by outliers.
- **b0 – Slope Of Trade Equity Regression Line.**
The equity curve is fitted by a straight line where $\text{Equity}_{\text{est}} = a_0 + b_0 * t$. $\text{Equity}_{\text{est}}$ is the straight line estimate of the Equity curve and **t** is the trade number. **b0** is the slope of the straight line. The dimensions of **b0** are dollars per trade.
- **r2 - Trade Equity Regression Trend Line Coefficient Of Correlation r2**
r2 is a measure of how well a straight line fits the equity curve. R2 goes from 0 to 100. An R2 of 100 means the equity curve fits a straight line exactly. In general, a high value of r2 is desirable because it indicates trade profit consistency.
- **dev - Median Of The Absolute Values Of (The Equity At Each Trade Minus The Equity Regression Trend Line)**
Dev is the median of all the absolute values of the deviations of the equity curve from the Equity straight line regression. This measure is similar to the standard deviation. However, the standard deviation squares each error(deviation of the equity curve from the Equity straight line regression) in it's sum it weights large deviations much more strongly and is highly distorted by outliers. I prefer to the robust median statistic.

Appendix 2 Power Walk Forward Optimizer Performance Metrics

- **mkr - Modified K-Ratio = $100 \cdot b0 / dev$.**
Lars Kestner developed the K-ratio in *Technical Analysis of Stocks and Commodities*, March 1996. The K-ratio compares reward to risk. Lars K-ratio used the Standard deviation from the trend line. I felt this gave too high a weight to the large profits and large losses so I modified the K-ratio by using the **dev** described above.
- **b1 - Slope Of Equity Curve Least Squares 2nd Order Polynomial Line Where $Equity_{est} = b1 \cdot i + b2 \cdot i^2$.**
The equity curve is fitted by a 2nd order polynomial where $Equity_{est} = b1 \cdot i + b2 \cdot i^2$. $Equity_{est}$ is the estimate of the Equity curve and **i** is the trade number. **b1** is the slope of the parabolic line. The dimensions of **b1** are dollars per trade. Many times the Equity curve doesn't fit a straight line very well. This is especially true if the equity curve is increasing or decreasing faster near the last trades than it was near the first trades. In this case, **b1** gives a better representation of the equity curve trend.
- **dy - Velocity Of Equity Curve Least Squares Parabola Line.**
This is a measure of how fast the equity curve is moving on the last trade. If **dy** is negative and **b1** is positive this indicates that the equity curve is trending down on the last trades. Since after the last test sample trade comes trades in real time, it's important to know what direction the equity curve was headed before you trade.
- **b2 - Acceleration Of Equity Curve Least Squares 2nd Order Polynomial Line Where $Equity = b1 \cdot i + b2 \cdot i^2$.**
The equity curve is fitted by a 2nd order polynomial where $Equity_{est} = b1 \cdot i + b2 \cdot i^2$. $Equity_{est}$ is the estimate of the Equity curve and **i** is the trade number. **b2** is the acceleration of the parabolic line. The dimensions of **b2** are dollars per trade². Many times the Equity curve doesn't fit a straight line very well. This is especially true if the equity curve is increasing or decreasing faster near the last trades than it was near the first trades. In this case, **b2** is a measure of how fast the slope of the equity curve is changing. If **b2** is positive the equity curve's slope is increasing upward meaning the equity is increasing faster than a straight line. If **b2** is negative, the equity curve's slope is decreasing meaning the equity will start decreasing some point in time if the equity continues to follow this parabolic curve.
- **r22 - Equity Least Squares 2nd Order Polynomial Line Coefficient Of Correlation r^2**
r22 is a measure of how well a least squares 2nd order polynomial line fits the equity curve. Note: for a 2nd order polynomial **r22** can be negative. This is because the coefficient of correlation is for straight lines. 2nd Order and higher polynomials would be considered nonlinear. An r^2 of 100 means the equity curve fits a parabolic exactly. In general, a high value of r^2 is desirable because it indicates trade profit consistency.
- **e-3 - End Equity Minus Equity 3 Trades before.**
This is another measure of the equity curve at the end. This shows what the equity trend is doing on the last three trades.
- **eq10 - Projected Equity 10 Trades in Future Using Curve Least Squares 2nd Order Polynomial Line/1000.**
This is another measure of the equity curve 10 trades in the future. The projected equity is divided by 1000. This shows what the best estimate of the equity would be if it followed the least squares parabolic line for ten trades into the future. This performance variable can also serve as a curve fit alert. If **eq10** is very high, this would indicate that the input parameters for this case have curve fit the noise and will not work well in the future. Using Excel you could exclude the Top 10% of **eq10** cases.

The Filter Output Columns are defined as follows

Row 1 is the PWFO Stub, File Start Date(070803), File End Date(081128), Number of weeks(t70) and Cost plus slippage of round trip trade (c=\$25).

Filter = The filter that was run. For example, b05llt|5:10 is: LR<=5, Number of trades/test section>=10.

Metric = The PWFO performance metric (defined on Appendix 2). For this filter, b05llt|5:10 Metric=b0 (Equity curve slope).

This b05llt|5:10-b0 filter produced the following average 70 week statistics on this line(row 3).

tOnp = Total out-of-sample(oos) net profit for these 70 weeks.

mOsp = median oos net profit for the 70 weeks

aOsp = Average oss net profit for the 70 weeks

aanp = Average oos profit per trade

aOnT = Average number of oos trades per week

B0 = The 70 week trend of the out-of-sample weekly profits

%P = The percentage of oos weeks that were profitable

t = The student t statistic for the 70 weekly oos profits. The higher the t statistic the higher the probability that this result was not due to pure chance

std = The standard deviation of the 70 weekly oos profits

llw = The largest losing oos week

eqDD = The oos equity drawdown

lr = The largest number of losing oos weeks in a row

= The number of weeks this filter produced a weekly result. Note for some weeks there can be no strategy inputs that satisfy a given filter's criteria.

b00 = The straight line trend of the oos equity curve in \$/week.

Blw = The maximum number of weeks the oos equity curve failed to make a new high.

BE = Break even weeks. Assuming the average and standard deviation are from a normal distribution, this is the number of weeks you would have to trade to have a 99% probability that your oos equity is above zero.

ndd = The normalized equity drawdown = 100*eqDD/tONet

Appendix 3 Power Walk Forward Optimizer Filters Output

tONet = Total out-of-sample net profit(tOnp) minus the total trade cost. $tONet = tOnp - \#*aOnT*Cost$.

Prob = The probability that the filter's tOnpNet was due to pure chance. For example, for row 3 where tOptNet=38933 there is a 1 in 1071 (1/0.000933) chance that the tOnpNet obtained by this filter was due to chance.
